THE COMMUNICATION APPREHENSION PERSPECTIVE

James C. McCroskey

The construct of communication apprehension (CA) has been central to the study of communication avoidance since 1970. In this paper we will examine the evolution of the CA construct and the most current conceptualization of that construct.

THE ORIGINAL CONCEPTUALIZATION

The original conceptualization of CA (McCroskey, 1970) viewed CA as "a broadly based anxiety related to oral communication." Subsequent writings have made only apparently minor modifications of this definition. More recent papers present the view that CA is "an individual's level of fear or anxiety associated with either real or anticipated communication with another person or persons" (McCroskey, 1977a, 1978).

This seeming consistency across time may be more apparent than real. Two conceptual modifications occurred. The first concerned the oral communication focus of CA and the other concerned whether CA was restricted to a trait conceptualization.

The Oral Focus of CA

In the original article in which I advanced the construct of CA, the focus clearly was on oral communication (McCroskey, 1970). Although in this article "communication" frequently was used without the "oral" qualifier, the earlier work in the areas of stage fright and reticence was acknowledged as the foundations upon which the CA construct was developed. Both of these areas focused exclusively on oral communication at that time.

In some subsequent writings the oral context of CA received less emphasis. Of particular importance were two research programs which were conducted under the general rubric of communication apprehension but which did not focus on speaking. The first was the research concerned with apprehension about writing (Daly & Miller, 1975). This stream of research, led by Daly and his associates, continues presently and has received considerable attention in the field of English. The measure developed by Daly and Miller, the Writing Apprehension Test (WAT), has been widely employed and found to have only a moderate correlation with my CA measures. The second research area was that concerned with apprehension about singing. While receiving far less attention than the articles and measures concerned with speaking and writing, research involving the Test of Singing Apprehension (TOSA) also discovered low correlations between the TOSA and CA measures (P. Andersen, J. Andersen, & Garrison, 1978).

In sum, over the decade since the CA construct has been advanced it has been substantially broadened. While it was originally restricted to talking, it now encompasses all modes of communication. Consequently, it should be

recognized that current instruments labeled as CA measures (notably the Personal Report of Communication Apprehension, PRCA: McCroskey, 1970, 1978, 1982) are restricted to oral CA, specifically apprehension about talking to or with others. My focus in the remainder of this paper is on this form of CA and when I use the term "CA" this will be my referent. I believe that most of what will follow will apply equally well to other forms of CA, however.

The Trait Conceptualization of CA

The original article which advanced the construct of CA included no explicit mention of whether it is a trait of an individual or a response to the situational elements of a specific communication transaction. However, the implication is clear that the construct was viewed from a trait orientation. Not only was the discussion directed toward a response generalized across situations and time, but also the measures advanced clearly focused on a trait-like pattern.

The overwhelming majority of the research studies employing the CA construct have taken a trait approach (McCroskey, 1977a). Many have referred to CA with terms such as "a trait-like, personality-type variable." More recently, the CA construct has been explicitly expanded to encompass both trait and situational views (McCroskey, 1977b). Some research has been reported which has investigated CA in both the trait and state form (eg., Richmond, 1978; Fiseli & Dallinger, 1981).

In sum, over the decade since the CA construct has been advanced it has been broadened substantially. While it originally was restricted to a trait orientation, it is now viewed as representing both trait and state approaches. While the original definition of CA restricts the construct to a trait perspective, the revised definition noted above is consistent with the broader view. It should be recognized, however, that the most popular measures of CA are restricted to a trait conceptualization. Research based on more situational perspectives must employ other instruments.

The Current Conceptualization of CA

Minor changes in the conceptualization of CA over the past decade have been noted. Such changes have appeared in the literature in a non-systematic manner. In addition, some elements of the CA construct have never been spelled out clearly. In the following sections the conceptualization of CA will be enunciated in four major areas: 1) types of CA, 2) causes of CA, 3) treatment of CA, and 4) effects of CA.

Types of CA

Considerable attention has been directed toward the distinction between trait and situational or state CA. This distinction has been quite helpful to researchers in the CA area in their attempt to distinguish older from newer approaches to this subject. Unfortunately, this distinction has come to be viewed as a dichotomy, a false dichotomy. To view all human behavior as emanating from either a trait-like, personality orientation of the individual or from the state-like constraints of a situation ignores the powerful interaction
of these two sources. No element of personality yet isolated by psychologists or others has been found to have universal predictability across all situations for all individuals. Similarly, no situation has yet been identified in which we can predict a universal behavior from all individuals. Even in life-threatening situations, people do not all behave alike. Thus, it is important that we reject this false state-trait dichotomy and view the sources of CA on a continuum. This continuum can be viewed as ranging from the extreme trait pole to the extreme state pole, although neither the pure trait nor state probably exists as a meaningful consideration. Four points along this continuum can be identified. Each of these points represents a distinct type of CA.

Trait-like CA. The term "trait-like" is used intentionally to indicate a distinction between this view of CA and one that would look at CA as a true trait. A true trait, as viewed here, is an invariant characteristic of an individual, such as eye color and height. No personality variable, and trait-like CA is viewed as a personality-type variable, meets this strict interpretation of "trait." After achieving adulthood, true traits of an individual are not subject to change. Trait-like personality variables, although highly resistant to change, can be and often are changed during adulthood. That CA is subject to such change is indicated clearly in the substantial research on treatment of people identified as having high CA (e.g., McCroskey, 1972).

Generalized-Context CA. Generalized-context CA is one step farther removed from pure trait than trait-like CA. CA viewed from this vantage point represents orientations toward communication within generalizable contexts. Fear of public speaking, the oldest of the CA conceptualizations, is illustrative of this type of CA. This view recognizes that people can be highly apprehensive about communicating in one type of context while having less or even no apprehension about communicating in another type of context.

Generalized-context CA is viewed as a relatively enduring, personality-type orientation toward communication in a given type of context. Although no taxonomy for generalized-context CA yet has received consensual acceptance in the literature, the one advanced by McCroskey and Richmond (1980), which is based on types of communication settings appears quite adequate. From this view there are four varieties of this type of CA—CA about public speaking, CA about speaking in meetings or classes, CA about speaking in small group discussions, and CA about speaking in dyadic interactions.

The first CA measure to receive wide acceptance by researchers, the Personal Report of Confidence as a Speaker (PRCS) developed by Gilkinson...
(1942), is illustrative of an instrument designed to tap this type of CA. Subsequent instruments for measuring public speaking anxiety reported by Paul (1966), and McCrosky (in Personal Report of Public Speaking Intolerance: PPSIs, 1970) also fall within this area. More recently, McCrosky and Richmond (1980) have offered instruments to measure each of the four varieties of generalized-context CA which they describe. As was the case with the trait-like CA measures described in the previous section, it is assumed that scores for an individual on any one of these measures will be highly similar across an extended period of time, barring an intervention program designed to alter the relevant CA level of a demand characteristic in measurement. These measures are distinguished from the previously noted trait-like measures in that they focus more narrowly on communication within a given type of context rather than on communication across contexts. It should not be surprising, however, to find moderate to moderately high correlations between the two types of measures. To the extent that a trait-like orientation toward communication actually exists, an appropriate measure of that orientation should be at least somewhat predictive of orientations within generalized contexts.

**Person-Group CA:** This type of CA represents the reactions of an individual to communicating with a given individual or group of individuals across time. People viewing CA from this vantage point recognize that some individuals and groups may cause a person to be highly apprehensive while other individuals or groups can produce the reverse reaction. For some people more apprehension may be stimulated by a peer or group of peers. For others, more apprehension may be stimulated by unfamiliar individuals or groups. A school teacher, for example, may be highly apprehensive about talking to her or his principal, but have no apprehension about talking to a student in her or his own class.

Person-group CA is viewed as a relatively enduring orientation toward communication with a given individual or group of people. It is not personality-based, but rather a response to situational constraints generated by the other person or group. Although presumed to be relatively enduring, this type of CA would be expected to be changed as a function of changed behavior on the part of the other person or group. Although people with high trait-like CA or high generalized-context CA would be expected to experience high CA with more persons and groups, knowledge of the levels of neither of these should be expected to predict the level of CA experienced with a given individual or group. In short, this type of CA is presumed to be more a function of the situational constraints introduced by the other person or group than by the personality traits of the individual. Length of acquaintance should be a major consideration here. While in early stages of acquaintance the personality orientations should be somewhat predictive, in later stages the situational constraints should be expected to over power these orientations (Richmond, 1978).

Few attempts to measure this type of CA have appeared in the literature. However, the state anxiety measure developed by Spielberger (1966), particularly as modified for this purpose by Richmond (1978), appears to be an excellent tool. It can be adapted readily for use with any person or group within any communication context.
Situational CA. This type of CA represents the reactions of an individual to communicating with a given individual or group of individuals at a given time. This is the most state-like of the types of CA. When we view CA from this vantage point we recognize that we can experience CA with a given person or group at one time but not at another time. For example, a student may experience little or no apprehension when going to a teacher to ask a question about an assignment, but be terrified if the teacher instructs the student to stay after class to meet with her or him.

Situational CA is viewed as a transitory orientation toward communication with a given person or group of people. It is not viewed as personality-based, but rather a response to the situational constraints generated by the other person or group. The level of this type of CA should be expected to fluctuate widely as a function of changed constraints introduced by the other person or group. Although people with high trait-like CA or high generalized-situational CA would be expected to experience high CA in more individual situations than would other people, knowledge of the levels of neither of these should be expected to be highly predictive of CA experienced by an individual in any given situation. On the other hand, level of person-group CA should be expected to be moderately highly related to situational CA. Person-group CA primarily is a function of the prior history of the individual with the given person or group. Such a history can be assumed to produce expectations which would influence the level of CA in the given situation involving communication with that person or group.

Measurement of situational CA has received little attention in the previous research. However, the Spielberger (1966) instrument as modified by Richmond (1978), as noted in the previous section, appears to be a very satisfactory tool for this purpose.

Figure 1 illustrates the four types of CA. As indicated in that figure, the three components of this conceptualization are context, receiver (person/group), and time. Time should be taken to represent more than just the hour or day of the communication. As conceived here this element includes the variability associated with topic, mood, health, and the like that are seen as changeable over time, as well as the literal element of time itself. Trait-like CA is seen as that which cuts across context, receiver, and time. Generalized-context CA is seen as that which is associated with a single type of communication context cutting across receiver and time. Person-group CA is seen as that which is associated with a single receiver or group of receivers cutting across context and time. Situational CA is seen as that which is specific to a given context with a given receiver at a given time. It should be recognized that the three components in this model could be combined to generate additional types of CA. However, at present, I do not believe such combinations provide useful insights.

Pathological CA. It is important that we recognize that the four types of CA discussed above do not reference different types of people. Rather, every individual is impacted by each type of CA to either a greater or lesser degree. It is a truly rare individual, if one actually exists, that never experiences
CA in any communication situation. Such an individual would be seen as evidencing pathological behavior, since fear is a natural human response to a truly threatening situation. Similarly, it is comparatively rare individual who experiences CA in all communication situations, although some such people do exist. With the exception of these rare individuals, even people with very high trait-like CA find some situations in which they can communicate comfortably. The most common of these situations involve communication with close friends. It is not unusual that close friends produce less apprehension as it is that people who produce less apprehension are allowed to become close friends while more threatening individuals are avoided.

Since in the previous literature much has been made of the pathological nature of high CA, high resistance, and high shyness, we need to consider what we should view as pathological, or abnormal, levels of CA. This distinction can be made both conceptually and empirically, although the distinctions are not fully isomorphic.

At the conceptual level, we view abnormal behavior to be that which is non-adaptive, non-responsive, or non-functional in the environment in which it is engaged. Normal individuals are sensitive to their environment, respond to its demands, and adapt their behavior so that they are a functional part of that environment. Experiencing fear or anxiety in a threatening situation and adapting by withdrawing or avoiding the threatening situation is normal. Experiencing no fear or anxiety in a non-threatening environment and continuing to function in that environment is normal. The reverse responses are abnormal. Experiencing low CA in the face of real danger and experiencing high CA when no real danger is present are both abnormal responses. If such responses become characteristic of the individual, they may be regarded as pathological and in need of professional help. The question, of course, is one of degree. Abnormal responses in one or a few circumstances certainly should not be grounds for a judgment of "pathological." Only when such behavior is a consistent pattern of the individual would such a judgement seem warranted. Most importantly, such judgments should not be restricted to only one end of the CA continuum. Extreme low CA can be just as abnormal as extreme high CA.

Empirically, the distinction between normal and abnormal is a bit more easily determined. I strongly endorse the empirical distinction made most frequently in the previous research. This distinction is based on the normal curve, an approximation of which is generated by scores on most of the common CA measures. People with scores beyond one standard deviation above or below the mean score of the population are identified as high or low in CA. In normally distributed scores, approximately 68 percent of the population falls within one standard deviation of the mean, with 16 percent scoring either one standard deviation higher and 16 percent scoring one standard lower. The latter two groups are, in fact, statistically significantly different at alpha = .05.

For research purposes, this is a particularly good distinction. The researcher can be reasonably assured that the people classified as "high" are truly different from those classified as "low." These two groups are the ones which theoretically should manifest differential behaviors related to the measure. Those in the middle, the "normals," actually may have no consistent
pattern of behavior, particularly if the measure is a personality-type measure. The middle scores most likely indicate that this is a facet of personality not highly associated with the behavior of these individuals. Other personality elements, or situational constraints, may completely dominate their behavior to the exclusion of this particular personality variable.

I originally introduced this system of classification into the literature as a function of observing groups of students brought into rooms for treatment of trait-like CA. I observed that groups of students composed entirely of individuals with scores beyond one standard deviation from the mean simply did not talk. The behavior of individuals in groups composed of people with scores between one-half and one standard deviation above the mean did not have such a consistent pattern. Some were totally non-communicative, but others were willing to interact. Thus, this classification scheme is not purely arbitrary. It does seem to have a behavioral justification.

Two cautions should be stressed, however. First, some samples may not be representative of the overall population. Therefore, the classification-by-standard-deviation procedure should be sensitive to the mean and standard deviation of the population norms rather than the particular sample studied. A sample of successful salespersons, for example, probably would include few people with high CA. Second, while this procedure is excellent for research involving comparatively large samples and based on aggregate data analyses, such a procedure is far too subject to measurement error to be applied to single individuals. Judgements about individuals should never be based on a single score or any scale. Rather, such a score should be only one of many factors to be considered. This is particularly important for people to recognize when developing or implementing intervention programs designed to alter high or low CA.

Causes of CA

The etiology of CA has received comparatively little attention in the literature. Varying writers have presented different views. The differences, however, are not so much a function of disagreement as they are of desperation. The best method of isolating causes of subsequent events generally is considered to be carefully controlled experimentation. Unfortunately, for ethical reasons, this method is highly restricted for investigations of the causes of CA. While we might ethically employ experimentation to investigate situational CA, almost no one would approve such experimentation with trait-like CA. The other types of CA fall within the grey area between these two types. Consequently, most research directed toward the etiology of CA has been performed in naturalistic environments. Such research is useful for establishing correlational associations, but it is fraught with potential error when attempting to infer causality. Much of the writing in this area is based more on speculation than on research. Regrettably, the following causal analysis will also have this characteristic. Hopefully, future research will provide insight into the validity of my speculations.

Previous causal analyses generally have been restricted to viewing either trait-like CA or situational CA. I will first present my positions in each of
these areas and then advance an etiological explanation which I believe may be applied to all types of CA.

Causes of Trait-like CA. Throughout the social sciences only two major explanations of the differential trait-like behaviors of individuals hold water: heredity and environment. Simply put, we can be born with it or we can learn it. I believe that both of these explanations can contribute to our understanding of the etiology of CA.

Although most early writers discounted heredity as a cause of trait-like CA out-of-hand, recent writers have grudgingly acknowledged that there indeed may be an hereditary contribution. Although no one has yet argued that there is a "CA gene," the work of social biologists, particularly their research with twins, has provided compelling evidence that something other than environmentally based learning is having an impact on human behavior tendencies. McCroskey and Richmond summarize the thrust of this research:

Researchers in the area of social biology have established that significant social traits can be measured in infants shortly after birth, and that infants differ sharply from each other on these traits. One of these traits is referred to as 'sociability,' which is believed to be a predisposition directly related to adult sociability—the degree to which we reach out to other people and respond positively to contact with other people. Research with identical twins and fraternal twins of the same sex reinforces this theoretical role of heredity. Identical twins are biologically identical, whereas fraternal twins are not. Thus, if differences between twins raised in the same environment are found to exist, biology (heredity) can be discounted as a cause in one case but not in the other. Actual research has indicated that biologically identical twins are much more similar in sociability than are fraternal twins. This research would be interesting if it were conducted only on twin infants, but it is even more so because it was conducted on a large sample of adult twins who had the opportunity to have many different and varied social experiences (1980, p. 6).

It is important to recognize that the work of the social biologists does not support the argument that heredity is the only cause of sociability, much less of CA, but rather suggests that heredity may be one of the contributing causes. Children, it seems, are born with certain personality predispositions or tendencies. No one has yet argued, not even the most ardent social biologists, that these predispositions or tendencies are unchangeable. Thus, what happens in the child's environment will have some impact on the predispositions and tendencies the child carries over into later life. However, because children are born with different predispositions and tendencies they will react differently to the same environmental conditions. This interaction of heredity and environment, then, is seen as the precursor of adult predispositions and tendencies such as CA.

Although heredity appears to be a meaningful contributor to trait-like CA, most writers allege that reinforcement patterns in a person's environment.

--8--
particularly during childhood, are the dominant elements. Although most of the views supporting reinforcement as a cause are based primarily on speculation or analogy, some available research is supportive (e.g., McCroskey & Richmond, 1978).

We can view the causal impact of reinforcement in at least two ways. The first is a fairly narrow, behaviorist view. If the child is reinforced for communicating, the child will communicate more. If the child is not reinforced for communicating, the child will communicate less. While this is a rather simple application of the general theory of reinforcement, and may serve to explain many communication behaviors, since it does not address the cognitions of the individual and CA is viewed as a cognitive variable, this explanation is less than satisfactory for our purpose.

The second way we can view the impact of reinforcement is as an adjunct of modeling. Modeling theory suggests that children (and to some extent adults) observe the communication behavior of others in their environment and attempt to emulate it. If their attempts are reinforced, they continue to behave in a similar manner. If they are not reinforced, they alter their behavior. Such an explanation seems to be a very good way of looking at the development of many communication behaviors, such as accent, dialect, and use of nonverbal behaviors. However, this explanation also ignores the cognitive element and thus does not address CA as conceived here.

While I agree that reinforcement is a central component in the development of CA, we do not believe that the behavioristic approaches outlined above can account for this relationship. My view of the place of reinforcement as a causal element in the development of CA will be outlined below when I consider the theory of learned helplessness.

Causes of Situational CA. While causal attributions for elements leading to the development of trait-like CA are based primarily on speculation and rather tenuous analogies, the causes of situational CA appear much clearer. In some cases it is a fairly narrow behaviorist view. If the child is reinforced for communicating, the child will communicate more. If the child is not reinforced for communicating, the child will communicate less. While this is a rather simple application of the general theory of reinforcement, and may serve to explain many communication behaviors, since it does not address the cognitions of the individual and CA is viewed as a cognitive variable, this explanation is less than satisfactory for our purpose.

behavior. CA is increased in formal situations because of the narrower confines for acceptable behavior. A similar impact results from interacting from a subordinate position. In such situations, appropriate behavior is defined by the person holding higher status. This is particularly important in evaluative settings, which are common in superior-subordinate communication situations.

Probably nothing can increase CA more than being conspicuous in one's environment. Giving a public speech is a prime example of being conspicuous. So is standing up to make a comment in a meeting or classroom. Similarly, being the new person in a social setting or meeting a new person can make a person feel conspicuous. Generally, the more conspicuous people feel, the more CA they are likely to experience.

Although not all people react to unfamiliarity in the same way, many people feel much more comfortable when communicating with people they know than when communicating with people they do not know. In general, as the degree of familiarity increases, the degree of CA decreases. To some extent, similarity has the same kind of impact. For most people, talking to others who are similar to themselves is easier than talking to people who are greatly different. There are major exceptions to this rule, however. Some people are the most uncomfortable when communicating to similar peers, because they are more concerned with the evaluations such people make than they are with people who are very different from themselves.

A moderate degree of attention from others is the most comfortable situation for most people. When people stare at us or totally ignore us when we are communicating, our CA level can be expected to rise sharply and quickly. In addition, if people become overly intrusive into our private feelings and thoughts, we can become very uncomfortable.

In recent work, Daly and Hailey (1980) have noted two elements that go beyond those advanced by Buss as causes of situational CA. These are degree of evaluation and prior history. When we are evaluated we tend to be more anxious than otherwise. For example, a student giving a talk in a public speaking class for a grade may be more apprehensive than the same student would be if he or she were giving the same talk to the same people at a meeting in a similar form. Of course, not everyone responds to evaluation in the same way. As Daly and Hailey have noted, good writers do better when being evaluated but poor writers do worse. This may also be true for oral communication, but no research is available which addresses this issue.

The final situative element, prior history, may be the most important of all, as we will note when we consider learned helplessness in the next section. If one has failed before it is increasingly likely that one will fear that he or she will fail again, hence be more apprehensive. On the other hand, success breeds both success and confidence, hence less apprehension.

In sum, there are a variety of elements in communication situations that can cause our CA to increase—whether we are high, moderate, or low in trait-like CA. Their absence, likewise, can lower our CA. Most of these elements are at best only marginally under our control. Thus, situational CA is
produced by others in our communication environment, and to a large extent controlled by them. Often, then, the only method of avoiding the unpleasant aspects of situational CA is to withdraw from or avoid such communication situations.

Learned Helplessness and Learned Responsiveness. Although the above causal explanations are useful in developing a fuller understanding of the etiology of CA, none of them are fully satisfactory. Work in the area of expectancy learning, particularly that concerning learned helplessness (Seligman, 1975), permits a causal explanation that can be applied to all types of CA since it takes into account both traits of the individual and the variety of situational demands the individual can confront.

My approach is a cognitive one. My underlying assumption is that people develop expectations with regard to other people and with regard to situations. Expectations are also developed concerning the probable outcomes of engaging in specific behaviors (like talking). To the extent that such expectations are found to be accurate, the individual develops confidence. When expectations are found to be inaccurate, the individual is confronted with the need to develop new expectations. When this continually recurs, the individual may develop a lack of confidence. When no appropriate expectations can be developed, anxiety is produced. When expectations are produced which entail negative outcomes which are seen as difficult or impossible to avoid, fear is produced. When applied to communication behavior, these latter two cases are the foundation of CA.

Reinforcement is a vital component of expectancy learning. Organisms form expectations on the basis of attempting behaviors and being reinforced for some and either not reinforced or punished for others. The most gestalt expectancy is that there is regularity in the environment. This forms the basis for the development of other, more specific expectations. When no regularity can be discovered in a given situation, either because none exists or there is too little exposure to the situation to obtain sufficient observation and reinforcement, the individual will be unable to develop a regular behavioral pattern for that situation which will maximize rewards and minimize punishments. Anxiety is the cognitive response to such situations, and the behavior is unpredictable to a large extent. However, non-behavior such as avoidance or withdrawal is possible, since even though this does not increase probability of obtaining reward, it decreases probability of receiving punishment in many instances. The organism essentially becomes helpless.

In the early animal research concerning helplessness, dogs were placed in an environment in which rewards and punishments were administered on a random schedule. After attempting behaviors to adapt to this environment, but receiving no regular response from the environment, the dogs retreated to a corner and virtually stopped behaving. They became helpless, and some actually died (Seligman, 1975).

An analog may be drawn with human communication behavior. We learn our communicative behavior by trying various behaviors in our environment and receiving various rewards and punishments (or absence of rewards or punishments) for our efforts. Over time and situations, we develop expectations
concerning the likely outcomes of various behaviors within and across situations. Three things can occur from this process. All can occur for the same individual. However, they may occur to greatly different degrees for different individuals. All are environmentally controlled. The three things that can occur are positive expectations, negative expectations, and helplessness. Let us consider each.

When we engage in communication behaviors that work (i.e., are reinforced), we achieve some desired goal, we develop positive expectations for those behaviors and they become a regular part of our communicative repertoire. While in the early childhood years much of this occurs through trial and error, during later stages of development cognition becomes much more important. We may think through a situation and choose communication behaviors which our previous experience suggests we should expect to be successful. Formal instruction in communication adds to our cognitive capacity to develop such expectations and choose appropriate behaviors. To the extent our behaviors continue to be reinforced, we develop stronger positive expectations and our communication behavior becomes more regularly predictable. In addition, we develop confidence in our ability to communicate effectively. Neither anxiety nor fear, the core elements of CA, are associated with such positive expectations.

The development of negative expectations follows much the same pattern as the development of positive expectations. We discover that some communication behaviors regularly result in punishment or lack of reward and tend to reduce those behaviors. During later stages of development, we may make cognitive choices between behaviors for which we have positive and negative expectations, the former being chosen and the latter rejected. However, we may find situations for which we have no behaviors with positive expectations for success. If we can avoid or withdraw from such situations, this is a reasonable choice. However, if participation is unavoidable, we have only behaviors with negative expectations available. A fearful response is the natural outcome. Consider, for example, the person who has attempted several public speeches. In each case, the attempt resulted in punishment or lack of reward. When confronted with another situation which requires the individual to give a public speech, the person will fear that situation. The person knows what to expect, and the expectation is negative.

The development of helplessness occurs when regularity of expectations, either positive or negative, is not present. Helplessness may be either spontaneous or learned. Spontaneous helplessness occurs in new situations. If the person has never confronted the situation before, they may be unable to determine any behavioral options. While this is much more common for young children, adults may confront such situations. For example, visiting a foreign country whose language is unknown to a person may place one in a helpless condition. Similarly, some people who are divorced after many years of marriage report they find themselves helpless in communication in the "singles scene." Such spontaneous helplessness generates strong anxiety feelings, and the behavior of people experiencing such feelings often is seen by others in the environment as highly aberrant.
Learned helplessness is produced by inconsistent receipt of reward and punishment. Such inconsistency may be either a function of true inconsistency in the environment or the inability of the individual to discriminate among situational constraints in the environment which produce differential outcomes. For example, a child may develop helplessness if the parent reinforces the child's talking at the dinner table some days and punishes it on other days. If the child is unable to determine why the parent behaves differently from day to day, the child is helpless to control the punishments and rewards. Similarly, the child may be rewarded for giving an answer in school but punished for talking to another child in the classroom. If the child is unable to see the differences in these situations, the child may learn to be helpless. When helplessness is learned, it is accompanied by strong anxiety feelings.

Learned helplessness and learned negative expectations are the foundational components of CA. The broader the helplessness or negative expectations, the more trait-like the CA. Inversely, the more situationally specific the helplessness or negative expectations, the more situational the CA. It should be stressed that helplessness and negative expectations (as well as positive expectations) are the product of an interaction of the behaviors of the individual and the responses of the other individuals in the environment. The development of the cognitive responses of the person, then, may be heavily dependent on the behavioral skills of that person, partly dependent on those skills and partly dependent on the responsiveness of the environment, or almost entirely a result of the environment. Thus, any hereditary component that may exist may have either a large or small impact on later cognitions, depending on the type of environment in which the hereditarily predisposed behaviors are performed.

Learned responsiveness is seen as the opposite of learned helplessness. When the individual is able to discern differences in situations and has developed positive expectations for communication behaviors between and across differing situations, the individual has learned to be communicatively responsive. Learned responsiveness is associated with neither fear nor anxiety, thus presents a circumstance antithetical to CA. Learned responsiveness can be the product of unsystematic learning in the natural environment or the direct result of formal communication instruction.

Treatment of CA

Our explanation of the etiology of CA has taken a cognitive perspective. Before turning our attention to possible treatments for CA, we should stress a distinction between what we will call "rational" CA and "non-rational" CA.

Rational levels of CA are produced by combinations of positive and negative expectations and helplessness or responsiveness that are consistent with views of an outside, objective observer's perceptions of reality. That is, the individual, for example, has a positive expectation for a behavior and an outside observer would agree that such a behavior should be expected to produce positive outcomes. Or, as another example, the individual feels helpless and knows of no behavior that would result in a desired outcome, and an outside observer would agree that that individual has no behavioral choice which would result in a positive outcome. Non-rational CA, on the other hand, is seen as
the unjustified expectations and helplessness or responsiveness of the individual, as viewed from the perspective of an outside, objective observer. For example, the individual may have negative expectations for a behavior, but an outside observer would see the behavior as highly likely to produce a desired outcome. Or, the individual feels very responsive, but the observer sees the person’s behavior as non-functional in the situation.

I stress this distinction in order to emphasize the fact that some people feel CA in situations where there is no objective reason for them to do so, while others may not experience CA even in situations in which they should. Past approaches to treatment, for the most part, have failed to make this distinction. It was presumed unreasonable to hold high levels of CA but reasonable to hold low levels of CA, thus only those people with high CA were seen as in need of treatment.

In my view, there are two major classifications of treatments, and they should be applied differentially depending on whether the CA level is rational or non-rational. Let me explain.

Treatments may be directed either toward communication behaviors or toward cognitions about communication behaviors. That is, our treatment focus can be on communication skills within or across contexts or on the apprehension about engaging in communication within or across contexts.

Four general conditions are illustrated in Figure 2. The figure represents two levels of communication skill, satisfactory and unsatisfactory, and two levels of CA, low and high. Both low CA/satisfactory skills and high CA/unsatisfactory skills are seen as rational conditions. Low CA/unsatisfactory skills and high CA/satisfactory skills are seen as non-rational conditions. Each condition provides different requirements for effective treatment.

Condition I, low CA/satisfactory skills, requires no treatment. People in this condition have rational cognitions, and most likely are reasonably effective communicators. The goal of all treatments is to move people from the other three conditions to this one.

Condition IV, high CA/unsatisfactory skills, also includes people with rational cognitions. They have unsatisfactory communication skills and are apprehensive about their communication. They have two problems, one behavioral and the other cognitive. No single solution is likely to overcome these problems and move these people to Condition I. If only their skills are improved, they will move to Condition III but still suffer from high CA. If only their CA is improved, they will move to Condition II but still suffer from inadequate skills. Thus, both their skill deficiencies and their CA require treatment. An analogy with basketball may help to clarify. People in Condition IV are poor foul shooters (say 30% in practice) and are very anxious about shooting foul shots in a game. If we overcome only the anxiety, they still can only shoot 30% in a game. If we only improve their shooting ability in practice, their anxiety will still cause them to miss in the game. To produce a good foul shooter, then, we need both to improve shooting accuracy and reduce anxiety. Returning to communication, people in this condition must develop better skills and reduce their apprehension to become more effective communicators.
Condition II, low CA/unsatisfactory skills, includes people with non-rational cognitions. These are people who should experience high CA, but they don't. We could increase their CA, thus making their cognitions more rational, but that would only move them to Condition IV, certainly not solving a problem but only making it worse. The treatment for people in this condition is directed toward improving communication skills. If skill levels are raised, people in this condition move to Condition I, the desired condition. To employ our basketball analogy, these people are poor foul shooters but not anxious about it. If we raise their skill level (say from 30% to 70%), we will produce a good foul shooter in the regular games.

Condition III, high CA/satisfactory skills, also includes people with non-rational cognitions. These are people who should not experience high CA, but they do. The treatment for people in this condition is directed toward reducing their CA level, thus moving them into Condition I. In our basketball analogy, these are people who shoot well in practice (say 70%) but choke and shoot poorly in the game (say 30%). If we overcome their anxiety, we will produce a good foul shooter in the regular games.

Treatment programs intended to produce effective communicators, then, are of two general types, those which are directed toward improving communication skills and those directed toward reducing CA. The different types of treatment programs are different solutions to different problems and should not be expected to have major effects on problems to which they are not directed. Reducing CA, for example, should not be expected to be associated with major increases in skill levels. Similarly, improving skills should not necessarily be expected to reduce CA, since CA level may be either rational or non-rational. For people with one problem, one treatment should be chosen. For people with both problems, two treatments should be chosen.

The specific nature of treatment programs is beyond my focus here. However, regular classroom instruction in communication skills (Phillips, 1977) are recommended. For CA problems, systematic desensitization (McCroskey, 1972; Paul, 1966) and cognitive restructuring (Fremouw & Scott, 1979) seem to be most appropriate. Various combinations of these treatments are possible. The choice of one should not be taken to exclude use of another.

Effects of CA

The effects of CA have been the target of extensive research, particularly concerning skill deficiencies and skill deficiencies. My focus here will not be on such specific variable research, but rather I will direct my attention toward theoretically more global effect patterns. The previous research, although extremely valuable for generating an understanding of how CA is manifested in ongoing communicative relationships of individuals, has been subject to considerable over-interpretation, if not mis-interpretation. Effects observed in aggregate data analyses often are seen as regular behavioral and outcome patterns for individual people with high or low CA. Such interpretations fail to recognize the high potential for the individual to deviate from the aggregate norm and the possibility of choosing from numerous behaviors, all of which would be theoretically consistent with
the individual's CA level. My concern here, therefore, will be directed toward the internal impact of CA, possible external manifestations of CA, and the role CA plays as a mediator between communicative competence and skill and ultimate communicative behavior.

Internal Impact of CA. As I have noted previously, CA is viewed from a cognitive rather than a behavioral perspective. Although CA indexes may have some behavioral implications, as I will note below, it is experienced by the individual internally. The only effect of CA that is predicted to be universal across both individuals and types of CA is an internally experienced feeling of discomfort. The lower the CA, the less the internal discomfort. Since people's cognitions are imperfectly related to their levels of physiological arousal, no physiological variable is predicted to be universally associated with CA across people or across types of CA.

The implications of this conceptualization of CA for both research and treatment cannot be overemphasized. Since CA is experienced internally, the only potentially valid indices of CA is the individual's report of that experience. Thus, self-reports of individuals, whether obtained by paper-and-pencil measures or careful interviews, obtained under circumstances where the individual has nothing to gain or avoid losing by lying, provide the only potentially valid measures of CA. Measures of physiological activation and observations of behavior can provide, at best, only indirect evidence of CA and, thus, are inherently inferior approaches to measuring CA. Thus, physiological and behavioral instruments intended to measure CA must be validated with self-report measures, not the other way around. To the extent such measures are not related to self-report measures, they must be judged invalid. Currently available data indicate such physiological measures and behavioral observation procedures have low to moderately low validity.

External Impact of CA. As noted above, there is no behavior that is predicted to be a universal product of varying levels of CA. Nevertheless, there are some externally observable behaviors that are more likely to occur or less likely to occur as a function of varying levels of CA. As behavioral outcomes of CA, we must keep in mind the distinction among the types of CA discussed earlier. Trait-like CA, for example, will be manifested in behavior in a given situation only as it interacts with the constraints of that situation. A person with high trait-like CA, for example, may behave in a manner no different from anyone else in a quiet conversation with a good friend. Similarly, a person with low trait-like CA may behave in a manner no different from anyone else if called to a meeting to be reprimanded by a superior. The behavioral manifestations of high CA we will discuss here, therefore, presuppose that CA actually is present to a sufficient degree in a given situation to trigger the behavior. The link is most direct for the most situational type of CA. For trait-like CA, the link is less tenuous. The behavioral prediction should only be assumed to be correct when considering aggregate behavioral indicators of the individual across time and across contexts.

Three patterns of behavioral response to high CA may be predicted to be generally applicable and one pattern can be described as sometimes present, but an atypical response pattern. The three typical patterns are communication
avoidance, communication withdrawal, and communication disruption. The atypical pattern is excessive communication. Let us consider each.

When people are confronted with a circumstance which they anticipate will make them uncomfortable, and they have a choice of whether or not to confront it, they may either decide to confront it and make the best of it or avoid it and thus avoid the discomfort. Some refer to this as the choice between "fight" and "flight." Research in the area of CA indicates the latter choice should be expected in most instances. In order to avoid having to experience high CA, people may select occupations which involve low communication responsibilities, may pick housing units that reduce incidental contact with other people, may choose seats in classrooms or in meetings that are less conspicuous, and may avoid social settings. At the lowest level, if a person makes us uncomfortable, we may simply avoid being around that person. Avoidance, then, is a common behavioral response to high CA.

Avoidance of communication is not always possible. In addition, a person can find herself or himself in a situation which generates a high level of CA with no advance warning. Under such circumstances, withdrawal from communication is the behavioral pattern to be expected. This withdrawal may be complete, i.e. absolute silence, or partial, i.e. talking only as much as absolutely required. In a public speaking setting, this response may be represented by the very short speech. In a meeting, class, or small group discussion, it may be represented by talking only when called upon. In a dyadic interaction, it may be represented by only answering questions or supplying agreeing responses with no initiation of discussion.

Communication disruption is the third typical behavioral pattern associated with high CA. The person may have disfluencies in verbal presentation or unnatural nonverbal behaviors. Equally as likely are poor choices of communicative strategies, sometimes reflected in the after-the-fact "I wish I had (had not) said . . . " phenomenon. It is important to note, however, that such behaviors may be produced by inadequate communication skills as well as by high CA. Thus, inferring CA from observations of such behavior is not always appropriate.

Over-communication is a response to high CA that is not common but is the pattern exhibited by a small minority. This behavior represents over-compensation. It may reflect the "fight" rather than the "flight" reaction, the attempt to succeed in spite of the felt discomfort. The person who elects to take a public speaking course in spite of her or his extreme stage fright is a classic example. Less easily recognizable is the individual with high CA who attempts to dominate social situations. Most of the time people who employ this behavioral option are seen as poor communicators but are not recognized as having high CA, in fact they may be seen as people with very low CA.

To this point we have looked at the typical behaviors of people with high CA levels. We might assume that the behaviors of people with low CA would be the exact reverse. That assumption might not always be correct. While people with low CA should be expected to seek opportunities to communicate rather than avoid them, and to dominate interactions in which they are a member rather than withdraw from them, people with low CA may also have disrupted communication
and over-communicate. The disruptions may stem from pushing too hard rather than tension, but the behaviors may not always be distinctly different to the observer. Similarly, the person who over-communicates engages in very similar behavior whether the behavior stems from high or low CA. While future research may permit us to train observers who can distinguish disrupted behavior resulting from high CA from that resulting from low CA and possibly distinguish between over-communication behaviors stemming from the two causes, these behaviors are, and probably will remain, indistinguishable by the average person in the communication situation.

CA and Communication Behavior. Without discounting a possible role for hereditary predispositions, I view communication behavior as other human behavior, as a learned response to one's environment. Since I wish to explore the role of CA as it relates to human communication behavior more generally, it is important to reiterate my assumptions about human learning. Following the lead of contemporary writers in educational psychology, I view human learning as composed of three domains. These are the cognitive (understanding or knowing), affective (feeling of liking or disliking), and psychomotor (the physical capability of doing) domains.

Because of inconsistent and confused use of terms within the communication literature, when I apply these domains to communication learning, it is important that I make a distinction between communication competence and communication skill. I see communication competence as falling within the cognitive domain and communication skill as falling within the psychomotor domain. More specifically, communication competence is "the ability of an individual to demonstrate knowledge of the appropriate communicative behavior in a given situation" (Larson, Backlund, Redmond & Barbour, 1978, p. 16). Communication competence, then, can be demonstrated by observing a communication situation and identifying behaviors that would be appropriate or inappropriate in that situation. Communication skill, on the other hand, involves actual psychomotor behavior. Communication skill is the ability of an individual to produce appropriate communicative behavior in a given situation. To be judged skilled, then, a person must be able to physically engage in appropriate behaviors.

The three components of desired communication learning, then, are communication competence (knowing and understanding appropriate communication behaviors), communication skill (being able to physically produce appropriate communication behaviors), and positive communication affect (liking and wanting to produce appropriate communication behaviors). Any desired impact on long-term behavior of the individual requires that production of all of these types of behaviors be achieved, whether by the "natural" environment or by a formal instructional system, or by some combination of the two.

CA can have a major impact in all three areas of communication learning, and, consequently, on the long-term behavior of individuals. High CA is seen as a potential inhibitor of the development of both communication competence and communication skill and as a direct precursor of negative communication affect. Low CA, on the other hand, is seen as a facilitator of the development of communication competence and communication skill and as a precursor of positive communication affect.
With regard to communication competence, high CA is projected as a barrier to accurate observation of the natural environment and sufficient experience within it and as a barrier to the formal study of communication. Not only do people try to avoid studying things which cause them discomfort, but also such discomfort may inhibit their learning when they do study it. The projected pattern for learning communication skills is seen in the same way. A major facet of psychomotor learning is practice. High CA will lead to less practice and possible misinterpretations of the outcomes of what practice is attempted. The impact of CA in terms of communication affect is even more direct. If we are fearful or anxious about something, we are not given to liking it. On the other hand, things that are not threatening are more likely to generate positive affect.

A major conclusion we can draw from this conceptualization of CA and communication learning is that high CA is highly associated with ineffective communication. As such, CA must be considered a central concern of any instructional program concerned with more effective communication as a targeted outcome, whether the program is labeled a program in communication competence or a program in communication skill. Basic competencies and basic skills cannot be separated from the problem of high CA.
FOOTNOTES

1. Criticisms of the 20- and 25-item PRCA instruments have been directed toward a heavy emphasis on items relating to public speaking in those instruments. This problem has been overcome in the most recent form of the measure, PRCA-24 (McCroskey, 1982). For this reason the new form is to be preferred over the earlier versions. This instrument permits four sub-scores as well as an overall score. The reliability of the instrument (internal) is estimated at .94 and the total score correlates with the earlier forms above .90. Data from over 25,000 subjects indicates the scores form a normal distribution with a mean of 65.6 and a standard deviation of 15.3.

2. It has been demonstrated repeatedly in the personality literature that any given personality variable may be relevant to behavioral prediction for some people but not for all people. People scoring in the mid-range of the measure are least predictable. For such people, the variable may be irrelevant and their behavior may be controlled by the situation and/or other personality characteristics. For a discussion of these problems, see Bem & Allen, (1974) and Bem & Funder, (1978).

3. These observations were made during data collection for the study reported by Ertle (1969).

4. For earlier research, see Clewenger. More recently, it has been found that although self-reported trait-like CA, as measured by the PRCA, is not highly correlated with physiological arousal, as measured by heart rate, the two combined are able to predict over 80 percent of the variance in self-reported state apprehension, as measured by a modification of the Spielberger state anxiety measure. The beta weights for the two predictors are nearly equal with little collinearity. See Behnke and Beatty (1981).

5. For suggestions for testing this type of prediction, see Jaccard and Daly (1980). Recent research reports validity coefficients in the neighborhood of .50 for the PRCA and a measure of shyness when tested in this way. See, McCroskey and Richmond (1981).

6. My use of "cognitive" previously referred to the distinction made in psychology between "cognitivists" and "behaviorists." This is a broader use of the term than the one relating to the domains of learning. The reader should avoid confusing the two usages.
